# An Experimental Comparison of Three Guiding Principles for the Detection of Salient Image Locations: Stability, Complexity, and Discrimination

Dashan Gao Nuno Vasconcelos Department of Electrical and Computer Engineering, University of California, San Diego dgao@ucsd.edu nuno@ece.ucsd.edu

## Abstract

We present an experimental comparison of the performance of representative saliency detectors from three guiding principles for the detection of salient image locations: locations of maximum stability with respect to image transformations, locations of greatest image complexity, and most discriminant locations. It is shown that discriminant saliency performs better in terms of 1) capturing relevant information for classification, 2) being more robust to image clutter, and 3) exhibiting greater stability to image transformations associated with variations of 3D object pose. We then investigate the dependence of discriminant saliency on the underlying set of candidate discriminant features, by comparing the performance achieved with three popular feature sets: the discrete cosine transform, a Gabor, and a Haar wavelet decomposition. It is show that, even though different feature sets produce equivalent results, there may be advantages in considering features explicitly learned from examples of the image classes of interest.

# 1. Introduction

Saliency mechanisms play an important role in the ability of biological vision systems to perform visual recognition from cluttered scenes. In the computer vision literature, the extraction of salient points from images has been a subject of research for, at least, a few decades. Broadly speaking, existing saliency detectors can be divided into four major classes.

The first, and most popular, treats the problem as one of the *detection of specific visual attributes*. These are usually edges or corners (also called "interest points"). For example, Harris [1] and Föstner [2] measure an auto-correlation matrix at each image location and then compute its eigenvalues to determine whether that location belongs to a flat image region, an edge, or a corner. While these detectors are optimal in the sense of finding salient locations of maximal stability with respect to certain image transformations, there have also been proposals for the detection of other low-level visual attributes, e.g. contours [3]. These basic detectors can then be embedded in scale-space [12], to achieve detection invariance with respect to transformations such as scale [13], or affine mappings [14].

A second major class of saliency detectors is based on more generic, *data-driven*, definitions of saliency. In particular, an idea that has recently gained some popularity is to define *saliency as image complexity*. Various complexity measures have been proposed: Lowe [4] measures complexity by computing the intensity variation in an image using the difference of Gaussian function; Sebe [5] measures the absolute value of the coefficients of a wavelet decomposition of the image; and Kadir [6] relies on the entropy of the distribution of local image intensities. The main advantage of the definitions in this class is a significantly greater flexibility, that makes them able to detect any of the lowlevel attributes discussed above (corners, contours, smooth edges, etc.) depending on the image under consideration.

A third formulation is to start from models of biological vision, and derive saliency detection algorithms from these models [7, 22]. This formulation has the appeal of its roots on what are the only known full-functioning vision systems, and has been shown to lead to interesting saliency behavior [7,22]. Interestingly, however, human experiments conducted by the proponents of some of these models have shown that, even in relatively straightforward saliency experiments, where subjects are 1) shown images that they have already seen and 2) simply asked to point out salient regions, people do not seem to agree on more than about 50% of the salient locations [22]. This seems to rule out all saliency principles that, like those discussed so far, are exclusively based on universal laws which do not depend on some form of 1) context (e.g. a higher level goal that drives saliency) or 2) interpretation of image content.

A final formulation that addresses this problem is directly grounded on the recognition problem, equating *saliency to discriminant power*: it defines salient locations as those that most differentiate the visual class of interest from all others [10,11,15]. Under this formulation, saliency requires a preliminary stage of feature selection, based on some suitable measure of how discriminant each feature is with respect to the visual classes that compose the recognition problem. In [15], it was shown that this can be done with reduced complexity and, once a set of discriminant features is available, discriminant saliency can be implemented with very simple, biologically inspired, mechanisms. It was also shown that discriminant saliency leads to higher classification accuracy than that obtained with saliency detectors based on "universal" definitions of salient points.

Various important aspects of discriminant saliency were, however, not fully investigated in [15]. For example, the repeatability of the salient points resulting from the proposed discriminant saliency detector was never compared to that of the salient points produced by the definitions of saliency which specifically seek optimality with respect to stability to image transformations. Also, given the close connection between saliency and the discriminant power of the selected set of features, it appears likely that the choice of the pool of candidate features from which this set is drawn can have a significant impact on the quality of the saliency judgments. The design of this initial feature set was not discussed in [15], where the discrete cosine transform (DCT) was adopted without much consideration for possible alternative feature spaces. In this work, we address these questions by presenting the results of a detailed experimental evaluation of the performance of various saliency detectors. This experimental evaluation was driven by two main goals: 1) to compare the performance of representative detectors from three of the saliency principles discussed above (stability, complexity, and discrimination), and 2) to investigate how the performance of the discriminant saliency detector proposed in [15] is affected by both the choice of features and the stability of the resulting salient points.

The paper is organized as follows. Section 2 briefly reviews the saliency detectors used in our comparison: the discriminant saliency detector of [15], a multiscale extension of the popular Harris interest point detector [1], and the scale saliency detector of [6]. Section 3 presents a comparison of the robustness of the salient locations produced by the three saliency detectors. It is shown that, somewhat surprisingly, discriminant saliency detection produces more stable salient points not only in the presence of clutter, but also for uncluttered images of objects subject to varying 3D pose. Section 4 then evaluates the impact of the feature set on the performance of the discriminant saliency detector, by considering the feature spaces resulting from the DCT, a Gabor, and a Haar wavelet decomposition. It is shown that, while the three feature sets perform similarly, there may be advantages in explicitly learning optimal features (in a discriminant sense) for the image classes of interest. Finally, some conclusions are presented in Section 5.

## 2. Saliency detection

We start with a brief review of the steps required to implement each of the saliency detectors considered in this work: the Harris saliency detector [1], the scale saliency detector of [6] and the discriminant saliency detector of [15].

### 2.1. Harris saliency

The Harris detector has its roots in the structure from motion literature. It is based on the observation that corners are stable under some classes of image transformations, and measures the degree of cornerness of the local image structure [1]. For this, it relies on the auto-correlation matrix,

$$M(x,y) = \sum_{(u,v)} w_{u,v} \nabla I(x+u,x+v) \nabla^T I(x+u,x+v)$$
(1)

where

$$\nabla I(\mathbf{x}) = (I_x(\mathbf{x}), I_u(\mathbf{x}))^T \tag{2}$$

is the spatial gradient of the image at location  $\mathbf{x} = (x, y)$ , and  $w_{u,v}$  is a low-pass filter, typically a Gaussian, that smoothes the image derivatives. The vanilla implementation of the Harris detector consists of the following steps.

- 1. the auto-correlation matrix is computed for each location **x**.
- 2. the saliency of the location is then determined by

$$S_H(\mathbf{x}) = \det[M(\mathbf{x})] - \alpha \operatorname{trace}^2[M(\mathbf{x})] \qquad (3)$$

where  $\alpha$  is set to 0.04 [1].

In our experiments, we rely on the following multiscale extension.

- 1. image is decomposed into a Gaussian pyramid [16].
- 2. a saliency map  $S_i(\mathbf{x})$  is computed at each pyramid level, using the Harris detector of size  $7 \times 7$ .
- 3. the saliency maps of different scales are combined into a multi-scale saliency map according to

$$S_H(\mathbf{x}) = \sum_{i=1}^k S_i^2(\mathbf{x}).$$
 (4)

A scale is also selected, at each image location, by searching for the pyramid level whose saliency map has strongest response.

4. Salient locations are determined by non-maximum suppression. The location of largest saliency and its spatial scale are first found, and all the neighbors of the location within a circle of this scale are then suppressed (set to zero). The process is iterated until all locations are either selected or suppressed. The Harris detector has been shown to achieve better performance than various other similar saliency detectors, when images are subject to 2D rotation, scaling, lighting variation, viewpoint change and camera noise [8].

## 2.2. Scale saliency

This method defines saliency as spatial unpredictability, and relies on measures of the information content of the distribution of image intensities over spatial scale to detect salient locations [6]. It consists of three steps.

- the entropy, H(s, x), of the histogram of local intensities over the image neighborhood of circular scale s, centered at x, is computed.
- the local maximum of the entropy over scales, H(x), is determined and the associated scale considered as a candidate scale, s<sub>p</sub>, for location x.
- 3. a saliency map is computed as a weighted entropy,

$$S_S(\mathbf{x}) = H(\mathbf{x})W(s_p, \mathbf{x}) \tag{5}$$

where

$$W(s, \mathbf{x}) = s \int \left| \frac{\partial}{\partial s} p(I, s, \mathbf{x}) \right| \mathrm{d}I$$

and  $p(I, s, \mathbf{x})$  is the histogram of image intensities.

Finally, a clustering stage is applied to the saliency map in order to locate the salient regions.

#### 2.3. Discriminant saliency

In [15], saliency is defined as the search for the visual attributes that best distinguish a visual concept from all other concepts that may be of interest. This leads to the formulation of saliency as a feature selection problem, where salient features are those that best discriminate between the target image class and all others. The saliency detector is implemented with the following steps.

1. images are projected into a K-dimensional feature space, and the marginal distribution of each feature response under each class  $P_{X_k|Y}(x|i), i \in \{0,1\}, k \in \{0,\ldots,K-1\}$ , is estimated by a histogram (24 bins were used in the experiments described in this paper). The features are then sorted by descending marginal diversity,

$$\mathbf{md}(X_k) = \langle KL[P_{X_k|Y}(x|i)||P_{X_k}(x)] \rangle_Y \quad (6)$$

where  $\langle f(i) \rangle_Y = \sum_{i=1}^M P_Y(i)f(i)$ , and  $KL[p||q] = \int p(s) \log \frac{p(x)}{q(x)} dx$  the Kullback-Leibler divergence between p and q.

Figure 1: Schematic of the saliency detection model.

2. features which are discriminant because they are informative about the background class (Y = 0) but not the class of interest (Y = 1), i.e.

$$H(X_k|Y=1) < H(X_k|Y=0)$$
 (7)

or that have too small energy to allow reliable inferences

$$Var(X_k) < T_v \tag{8}$$

are eliminated.

- 3. features of largest marginal diversity are selected as salient for the class of interest. The number of features that are salient for each class is determined through a cross-validation procedure [15].
- 4. a saliency map is generated by a biologically inspired saliency architecture (shown in Figure 1) which consists of the projection of the image into the subspace spanned by the salient features, and the combination of the resulting projections  $R_i(\mathbf{x})$  into a saliency map according to

$$S_D(\mathbf{x}) = \sum_{i=1}^n \omega_i R_i^2(\mathbf{x}),\tag{9}$$

5. salient locations are determined by a non-maximum suppression stage which sets the scale of each salient location to the spatial support of the feature of largest response at that location.

The method is made scale adaptive by including features of different size in the candidate feature set.

## 3. Stability of salient locations

There are various ways to evaluate the goodness of salient locations (see [8] for a detailed review). One property that is usually desirable is stability of these locations under image transformations. In this work we consider two such measures: 1) the repeatability of salient locations under pose changes, i.e. the stability over a collection of images taken

under varying viewing conditions, and 2) the robustness of salient locations in the presence of background clutter and intra-class variation, e.g. variable appearance of different objects in the same class. Note that although repeatability under pose change is important for applications such as object tracking and 3-D reconstruction, the second criterion is more relevant for the recognition from cluttered scenes.

## **3.1.** Stability with respect to clutter and intraclass variation

For these experiments we relied on the Caltech database, which has been proposed as a testbed for unsupervised object detection in the presence of clutter [18]. We adopted the experimental set up of [18]: four image classes, faces(435 images), motorbikes(800 images), airplanes (800 images), and rear view of cars (800 images), were used as the classes of interest (Y = 1)<sup>1</sup>. The Caltech class of "background" images was used, in all cases, as the "other" class (Y = 0).

Although there is a fair amount of intra-class variation in the Caltech database (e.g., the faces of different people appear with different expressions and under variable lighting conditions), there is enough commonality of pose (e.g., all faces are shown in frontal view) to allow the affine mapping of the images into a common coordinate frame, which can be estimated by manually clicking on corresponding points in each image. In this common coordinate frame it is possible to measure the stability of salient locations using a protocol proposed in [9] and which is adopted here. In particular, a salient location is considered a match to a reference image if there exists another salient location in the reference image such that 1) the distance between the two locations is less than half the smallest of the scales associated with them, and 2) the scales of the two locations are within 20%of each other. The average correspondence score Q is then defined as

$$Q = \frac{Total \ number \ of \ matches}{Total \ number \ of \ locations}.$$
 (10)

Suppose N locations are detected for each of the M images in the database. The score  $Q_i$  of reference image i is the ratio between the total number of matches between that image and all other M-1 images in the database, and the total number of salient locations detected in the latter, i.e.,

$$Q_i = \frac{N_M^i}{N(M-1)}.$$
 (11)

The overall score Q is the average of  $Q_i$  over the entire database. This score is evaluated as a function of the number of detected regions per image.

Figure 2: Stability in the presence of clutter and intra-class variability for (a) faces, (b) motorbikes, and (c) cars.

The performance of the three saliency detectors, discriminant saliency  $(S_D)$ , Harris saliency  $(S_H)$ , and scale saliency  $(S_S)$ , was compared on the three Caltech object classes (face, motorbike, and rear views of cars) for which alignment ground truth is available [9]. As illustrated by Figure 2, discriminant saliency achieved significantly better performance than the other two methods for all classes. A more careful analysis reveals two interesting trends. First,  $S_D$  achieved a high stability score with only a few salient locations, indicating that the top salient locations tend to be located more on the objects of interest than on the background. This is especially true for faces, where the matching score with only the first salient location is 37%. Second, while increasing the number of salient locations improves the matching score of the top salient locations, the discriminant power of additional locations starts to decrease at some point, and the matching score tends to decrease after that (see Figure 2 (b) and (c)). This, once again, indicates that discriminant saliency provides more information about the objects of interest than the other methods. Figure 5 presents

<sup>&</sup>lt;sup>1</sup>the Caltech image database is available at http://www.vision.caltech.edu/html-files/archive.html

some examples of salient locations detected by discriminant saliency on Caltech, illustrating how the salient locations are detected robustly, despite substantial changes in appearance and significant clutter in the background.

### 3.2. Stability under 3-D object rotation

The Columbia Object Image Library (COIL-100) [21] is an appropriate database to evaluate the stability of salient locations under 3-D rotation. It contains images from a set of 100 objects, 720 images from each object, obtained by rotating the object in 3D by 5 degrees between consecutive views. To avoid the loss of consistence of distinctive features due to large view-angle change (e.g. the eyes of a subject are not visible from the rear), six consecutive images were used for training and the next three adjacent images (after subsampling so that there are 10 degrees of rotation between views) were used for testing. Sixty objects in the library were used and, for each image, the top ten salient locations were kept. A salient location was considered stable if it appeared in all three test images. The stability was measured by (10).

Table 1 lists the performance of the three saliency detectors. Once again, discriminant saliency performed best. This is somewhat surprising, since stability was not directly enforced in the computation of discriminant saliency, and it outperforms Harris, which is designed to be optimal from a stability standpoint. A perfectly reasonable explanation is, however, supported by a closer investigation of the detected salient locations. As can be seen from the examples shown in Figure 3, the locations produced by discriminant saliency tend to be locations that maintain a consistent appearance as the object changes pose. This makes intuitive sense since, rather than searching for "salient" points from individual views, discriminant saliency selects features that are "consistently salient" for the whole set of object views in the image class. Or, in other words, under the discriminant saliency principle good features are features that exhibit small variability of response within the class of interest (while also discriminating between this class and all others). This leads to robust saliency detection if the training set is rich enough to cover the important modes of appearance variability.

# 4. Influence of features on discriminant saliency

The good performance of discriminant saliency in the previous set of experiments, motivated us to seek possible im-

	$S_D$	$S_H$	$S_S$
Stability(%)	74.7	71.6	52.2

Table 1: Stability results on the Columbia objects image database.

Figure 3: Examples of salient locations detected by  $S_D$  for COIL.

provements to this model. For example, in [15], the authors adopted the discrete cosine transform (DCT) feature set without extensive discussion as to why this feature set should be the one of choice. We studied the dependence of discriminant saliency on the underlying features, by comparing the performance of the DCT to that of two other feature sets.

## 4.1. Feature sets

A DCT of size *n* is the orthogonal transform whose  $(n \times n)$  basis functions are defined by:

$$A(i,j) = \alpha(i)\alpha(j)\cos\frac{(2x+1)i\pi}{2n}\cos\frac{(2y+1)j\pi}{2n},$$
(12)

where  $0 \leq i, j, x, y < n$ ,  $\alpha = \sqrt{1/n}$  for i = 0, and  $\alpha = \sqrt{2/n}$  otherwise. According to [15] there are two main reasons to adopt these features. First, they have been shown to perform well on various recognition tasks [17]. Second, as can be seen from Figure 4 (a), many of the DCT basis functions can be interpreted as detectors for various perceptually relevant low-level image attributes, including

Figure 4: Basis functions for (a) DCT, (b) Gabor, and (c) Haar features.

edges, corners, t-junctions, and spots. In our experiments, we started by decomposing each image into a four-level Gaussian pyramid. We then computed a multiscale set of DCT features by projecting each pyramid level onto the  $8 \times 8$  DCT basis functions.

The second feature set is based on a Gabor filter bank, which is a set of orientation-specific, band-pass filters. A two dimensional Gabor function can be generally written as

$$g(x,y) = K \exp(-\pi (a^2 (x - x_0)_r^2 + b^2 (y - y_0)_r^2)) \\ \exp(j(2\pi F_0 (x \cos \omega_0 + y \sin \omega_0) + P))$$
(13)

where

$$(x - x_0)_r = (x - x_0) \cos \theta + (y - y_0) \sin \theta (y - y_0)_r = -(x - x_0) \sin \theta + (y - y_0) \cos \theta.$$

Studies of biological vision have shown that Gabor filters are a good approximation to the sensitivity profiles of neurons found in visual cortex of higher vertebrates [19]. For this reason, Gabor filters have been widely used in image analysis for over a decade. The Gabor filter dictionary adopted in these experiments consists of 4 scales and 8 directions (evenly spread from 0 to  $\pi$ ), as shown in Figure 4(b). The features are also made scale-adaptable by applying to a four-level Gaussian pyramid.

The third feature set is one that has recently become very popular in the computer vision literature, due to its computational efficiency: the Haar decomposition proposed in [20] for real-time object detection. The computational efficiency of this feature set makes it equally attractive for the saliency problem. As shown in Figure 4(c), five kinds of Haar features were considered in the experiments reported in this work. By varying the size and ratio of the width and height of each rectangle, we generated a set with a total of 330 features.

## 4.2. Classification of saliency maps

To obtain an objective comparison of the different saliency detectors, we adopted the simple classifier-based metric suggested in [15]. This metric consists of feeding an histogram of saliency map intensities to a classifier and measuring the probability of classification error. It quantifies how relevant the extracted saliency information is for recognition purposes. Following [15], we relied on a support vector machine (SVM) to classify the saliency histograms. The classification experiments were performed on the Caltech database, and performance measured by the receiver-operating characteristic (ROC) equal-error-rate (i.e. p(Falsepositive) = 1 - p(Truepositive)).

The classification results obtained with the different feature sets are presented in Table 2. Although the DCT features achieved the overall best performance, the other two feature sets were also able to obtain a high classification accuracy. For example, discriminant saliency based on any of the three feature sets has performance significantly superior to that achieved by the Harris and scale saliency detectors. While this implies that discriminant saliency is not overly dependent on a unique set of features, these results also support the argument that a feature set with enough variability to represent the distinctive characteristics of the class of interest can improve performance. Note, for example, that the Haar features achieve the best performance in the "Airplanes" class. This is not surprising, since a distinctive feature for this class is the elongated airplane body which, in most images, is lighter than the background. While the DCT set lacks a specific detector for this pattern, the bottom left feature of Figure 4 (c) is one such detector, explaining the best performance of the Haar set in this case. An interesting question for future research is, therefore, how to augment the discriminant saliency principle with feature extraction, i.e. the ability to learn the set of features which are most discriminant for the class of interest (rather than just selecting a subset from a previously defined feature collection).

Dataset	$S_D$ DCT	$S_D$ Gabor	$S_D$ Haar	$S_H$	$S_S$
Faces	97.24	95.39	93.09	61.87	77.3

# 5. Conclusion

In this work, we have presented an experimental comparison of the performance of various saliency detectors. In particular, we have considered detectors representative of three different principles for the detection of salient locations: locations of maximum stability with respect to image transformations, locations of greatest image complexity, and most discriminant locations. Our results show that discriminant saliency performs better not only from the points of view of 1) capturing more relevant information for classification, and 2) being more robust to image clutter, but also 3) by exhibiting greater stability to image transformations associated with variations of 3D object pose. We have also investigated the dependence of discriminant saliency with respect to the underlying set of candidate discriminant features and found that, even though different feature sets (DCT, Gabor, Haar) worked similarly well, there may be advantages in considering feature sets explicitly learned from examples of the image classes of interest. The design of algorithms to optimally learn such features in a discriminant sense remains a topic for future work.
